ABSTRACT

A remarkable result of the Wilkinson Microwave Anisotropy Probe (*WMAP*) observations is that the universe was significantly reionized at large redshifts. The standard explanation is that massive stars formed early and reionized the universe around redshift $z \approx 17$. Here we explore an alternative possibility, in which the universe was reionized in two steps. An early boost of reionization is provided by a decaying sterile neutrino, whose decay products, relativistic electrons, result in partial ionization of the smooth gas. We demonstrate that a neutrino with a mass of $m_\nu \sim 200$ MeV and a decay time of $t \sim 4 \times 10^{15}$ s can account for the electron scattering optical depth $\tau \approx 0.16$ measured by *WMAP* without violating existing astrophysical limits on the cosmic microwave and gamma ray backgrounds. Reionization is then completed by subsequent star formation at lower redshifts. This scenario alleviates constraints on structure formation models with reduced small-scale power, such as those with a running or tilted scalar index, or warm dark matter models.

1. INTRODUCTION

The recent observations by the Wilkinson Microwave Anisotropy Probe (*WMAP*) have clarified many issues related to the energy content of the universe, and determined key cosmological parameters to unprecedented precision (Spergel et al. 2003). One of the interesting results of *WMAP* comes from the cross-correlation between the temperature and E-mode polarization angular power spectra, which has shown that the electron scattering optical depth is large, $\tau_e = 0.16 \pm 0.04$ (Kogut et al. 2003). This high value can be explained by an early phase of star-formation, reionizing the universe in a single step at redshift $z = 17 \pm 0.3$. A series of papers following the *WMAP* results have described this scenario in detail (Wyithe & Loeb 2003b; Haiman & Holder 2003; Ciardi et al. 2003; Somerville & Livio 2003; Fukugita & Kawasaki 2003; Sokasian et al. 2003; Cen 2003b; Chiu et al. 2003). The implications of the *WMAP* results for the stellar reionization scenario has been reviewed recently in Haiman (2003).

In structure formation models in the currently favoured spatially flat cosmologies with dark energy and cold dark matter (Λ CDM), the earliest large dark matter structures appear at redshift $z \sim 20$. Stellar reionization is therefore quite natural, provided that these early structures are associated with sites of efficient star formation and ionizing photon production. Nevertheless, an optical depth as high as $\tau_e = 0.16$ requires efficiencies that are higher than expected from the known population of galaxies at lower redshifts. Most pre-*WMAP* studies of cosmological reionization favoured a reionization epoch around $z = 7 - 12$ (Haiman & Loeb 1997, 1998; Gnedin & Ostriker 1997), although significant reionization at higher redshifts was predicted in models that included an early generation of massive, metal-free stars (Cen 2003a; Wyithe & Loeb 2003a).

Previous evidence based on the spectra of distant quasars have shown that the intergalactic medium (IGM) is highly ionized at least out to redshifts $z \sim 6$. However, the most natural interpretation of the strong HI absorption seen in the spectra of the highest redshift quasars (Becker et al. 2001; Fan et al. 2003) in the Sloan Digital Sky Survey (SDSS) is that reion-

ization is being completed near the redshifts of these sources, at $z \sim 6 - 7$. The *thermal* history of the IGM contains additional evidence that reionization was completed at $z < 10$ (Hui & Haiman 2003; Theuns et al. 2002).

Post-*WMAP* analyses (e.g. Haiman & Holder 2003; Cen 2003b; Wyithe & Loeb 2003b) indicate that such an early generation of metal-free stars, or an equivalent 'boost' by a factor of $\gtrsim 20$ in the efficiency parameters of the $z \sim 20$ ionizing source population, is required relative to that of the $z \sim 6$ source population, in order to *simultaneously* match the *WMAP* value of $\tau_e = 0.16$ and the SDSS quasar data. It is worth noting that stellar reionization would be much less realistic in cosmologies with low small-scale power, in which the onset of structure formation is delayed, such as those with a running or tilted scalar index (Hannestad et al. 2002; Haiman & Holder 2003; Somerville et al. 2003), or warm dark matter models (Barkana, Haiman & Ostriker 2001; Yoshida et al. 2003; Somerville et al. 2003b; Spergel et al. 2003).

In summary, in order to explain the large value of $\tau_e = 0.16$, the standard stellar reionization scenario requires 1) a hitherto unobserved early stellar population, and 2) small-scale dark matter structure to be in place by $z \sim 20$. While these requirements are reasonable, whether they are satisfied remains to be tested with future data. In this paper, we pose the question: *are there alternative possibilities to significantly reionize the universe at $z \sim 20$?* One such alternative that avoids the above requirements is reionization by decaying particles. Sciama (1982) suggested the possibility of photo-reionization from radiatively decaying particles where the decaying particle has a mass of few tens of eV. Related issues were discussed thoroughly in numerous papers (early studies include Cabibbo et al. 1981; Salati and Wallet 1981; Rephaeli and Szalay 1981). However, these types of particle physics candidates, such as light photinos and gravitinos, are now excluded by modern accelerator data (Hooper and Plehn 2002; Dreiner et al. 2003). Another interesting candidate was a decaying active neutrino (Sciama 1990) which was proposed both as a dark matter candidate and also to reionize the universe. However, current cosmological data excludes such massive neutrinos (Adams et al. 1998;

Bowyer et al. 1999; Spergel et al. 2003).

Let us imagine the general case of a cosmologically significant particle, with the property that it decays around a redshift $z \sim 20$. The decay products could have energies high enough to reionize the light elements. If this hypothetical particle is sufficiently abundant, then it may explain the high value of the optical depth, without the need for stars to reionize the universe early. In such a scenario, normal stellar populations could form at lower redshifts ($z \lesssim 10$), with the usual efficiencies, seeded in dark matter structures on the better understood scales of dwarf galaxies, and account for the completion of reionization epoch that appears to be occurring at $z < 10$.

In this paper, we turn to particle physics and describe a specific example for such a particle that is both viable (on particle physics grounds) and satisfies existing astronomical constraints. In practice, the choice of a specific particle candidate turns out to be severely limited by astronomical observations, such as big bang nucleosynthesis (BBN), the diffuse gamma-ray background (DGB), and the stringent limit on the deviation of the spectrum of the cosmic microwave background (CMB) from a pure Planck shape. Here we present a model which relies on a minor extension of the standard model: introducing a heavy sterile neutrino which mixes with one of the active neutrinos. Heavy sterile neutrinos are expected in extensions of the standard model, in order to give masses to the active (light) neutrinos through the see-saw mechanism (Yanagida 1980; Mohapatra and Senjanovic 1980). The neutrino masses we will consider below are somewhat smaller than invoked for the see-saw mechanism. Our particle should therefore be regarded as a new independent sterile neutrino (see e.g. Hansen 2001; Dolgov 2003, for reviews on heavy sterile neutrinos in cosmology). For the purpose of reionization, the main novelty of this particle is that its decay products are energetic electrons, rather than photons. As we shall see below, this makes it possible to achieve reionization without violating other astrophysical observations.

The rest of this paper is organized as follows. In § 2, we describe the candidate particle we propose, quantify the expected amount of reionization, and show that the particle obeys various astrophysical constraints. In § 3, we discuss the cosmological implications of this new particle, and in § 4, we offer our conclusions. Throughout this paper, we adopt the background cosmological parameters as measured by the WMAP experiment, $\Omega_m = 0.29$, $\Omega_\Lambda = 0.71$, $\Omega_b = 0.047$, $h = 0.72$ (Spergel et al. 2003, Tables 1 and 2).

2. DECAYING STERILE NEUTRINO

2.1. Production and Decay Mechanisms

We will now discuss some details of the production and decay mechanism of the heavy sterile neutrino we propose. Our main goal is to demonstrate that particle physics can provide a viable decaying particle whose decay products (energetic electrons in our case) can reionize the universe early, without violating other observations. We do not attempt a comprehensive analysis of all possible particle physics candidates here; indeed, we expect that there could be other particle candidates which could similarly account for early reionization.

Let us consider a standard two-neutrino oscillation scheme, where one of the active neutrinos, $\nu_\alpha = \nu_e, \nu_\mu$ or ν_τ , mixes with a heavy mainly sterile neutrino, ν_s ,

$$\begin{aligned}\nu_\alpha &= \cos\theta \nu_1 + \sin\theta \nu_2, \\ \nu_s &= -\sin\theta \nu_1 + \cos\theta \nu_2,\end{aligned}\quad (1)$$

where ν_1 and ν_2 are assumed to be the light and heavy mass eigenstates respectively, and θ is the vacuum mixing angle. Let the light neutrino be massless and the heavy neutrino have mass m . We will consider very small mixing angles, and hence refer to the light neutrino mass eigenstate as the active neutrino and the heavy one as the sterile neutrino.

If the sterile neutrino has a mass in the range 140-500 MeV, then the dominant decay channel (Astier et al. 2001) is

$$\nu_s \rightarrow l + \pi, \quad (2)$$

where the lepton, l , can be either an electron, a positron, or a neutrino. For larger masses, new decay channels open up (including kaons, eta, etc.), and the considerations below become more complicated. For smaller masses the decay products include too few photons and electrons for our purpose. The rate for the reaction $\pi_0 \rightarrow \nu\bar{\nu}$ was calculated by Fischbach et al. (1977) (see also Kalogeropoulos et al. 1979), and the result was converted to the reaction $\nu_s \rightarrow \nu_\alpha + \pi_0$ by Dolgov et al. (2000). Here we also need to include the charge current reactions

$$\begin{aligned}\nu_s &\rightarrow e^- + \pi_+, \\ \nu_s &\rightarrow e^+ + \pi_-, \end{aligned}\quad (3)$$

and we find the lifetime

$$\begin{aligned}\tau_{\text{decay}} &= \left[(2+r^2) \frac{(G_F f_\pi \sin\theta)^2}{8\pi} m (m^2 - m_\pi^2) \right]^{-1} \\ &\approx \frac{1.2 \times 10^{-9} \text{sec}}{M(M^2 - 1) \sin^2\theta},\end{aligned}\quad (4)$$

where $r^2 \approx 0.2$, G_F is the Fermi constant, $f_\pi = 131$ MeV, and the masses $M = m/m_\pi$ are all in units of the charged pion mass, $m_\pi = 139.7$ MeV. When we express the decay time, τ , in units $10^{15} \text{ sec} \approx 30 \text{ Myr}$, then this equation becomes

$$\tau_{15} M(M^2 - 1) \sin^2\theta = 1.2 \times 10^{-24}. \quad (5)$$

The reactions (3) directly provide us with a significant number of highly relativistic electrons and positrons, which we can use to reionize the universe early. Some of the energetic positrons could annihilate with the thermal (and also with the much more dilute, energetic) electrons, but the resulting photons would have mean free path larger than the Hubble distance. Such annihilation would change our result slightly at worst, by reducing the number of ionizations.

Let us now turn to the production and abundance of the sterile neutrinos. These neutrinos are produced through standard neutrino oscillations while they are still relativistic, at a temperature of about 7 GeV, when there are about 90 degrees of freedom in the plasma (Kolb and Turner 1990). For mixing with electron neutrinos, the fraction of sterile neutrinos to active ones is (Dolgov & Hansen 2001)

$$\frac{n_s}{n_\alpha} = 4.0 \times 10^9 \sin^2\theta M. \quad (6)$$

For mixing with muon or tau neutrinos, the numerical coefficient in front is instead 5.6. If the sterile state is mixed with both electron and muonic (tau) neutrinos, then the produced number increases correspondingly. We thus assume that there is no thermal relic abundance of these sterile neutrinos. Specific models with such properties exist (Bento & Berezhiana 2001; Berezhiani & Mohapatra 1995), however, other production mechanisms can produce a significantly higher abundance of sterile neutrinos (Sarkar 1996; Mohapatra and Sciama 1998).

2.2. Reionization Efficiency

Let us next estimate the amount of hydrogen which can be reionized by the decay products. The universe is transparent to the vast majority of photons from the process $\pi_0 \rightarrow 2\gamma$, since these photons have energies above $m_\pi/2$. Since the abundance of these sterile neutrinos is about 15 orders of magnitude below that of a thermalized neutrino, one easily sees (Kolb and Turner 1990) that the diffuse gamma background is many orders of magnitude larger than the photons resulting from both π_0 and $\pi^\pm$. We can therefore ignore this fraction of the decay products and consider the fate of the relativistic decay electrons instead. These electrons are injected into the IGM at redshift $z \sim 20$ (i.e. at the redshift where the decay time equals the age of the universe) with energies of about $E_e = (m_\pi/2)(M-1)$, i.e. between $0 < E_e < 180$ MeV. The relevant interactions for such electrons with the background gas and with the CMB have been summarized in, e.g. Oh (2001). For our purposes, the two important processes are inverse Compton scattering with CMB photons, and collisional ionization of neutral hydrogen. The mean free path to Compton scattering is

$$\lambda_C = (\sigma_T n_\gamma)^{-1} \sim 4 \times 10^{17} [(1+z)/21]^{-3} \text{cm}, \quad (7)$$

where σ_T is the Thomson cross section and n_γ is the CMB photon number density. The mean free path to collisionally ionizing hydrogen is

$$\lambda_H = (\sigma_H n_H)^{-1} \sim 1.4 \times 10^{24} (E_e/100 \text{MeV}) [(1+z)/21]^{-3} \text{cm}, \quad (8)$$

where σ_H is the electron impact ionization cross section (Shull & van Steenberg 1985, equation A2; we have ignored a small logarithmic correction), and $n_H = 2 \times 10^{-3} [(1+z)/21]^3 \text{cm}^{-3}$ is the neutral hydrogen density. Since $\lambda_C \ll \lambda_H$, the electrons will undergo repeated Compton scatterings with the CMB photons. At each scattering event, the CMB photon will be up-scattered to the energy $E_\gamma \sim (4/3)\gamma^2 E_{\gamma,0} \sim 300(E_e/100 \text{MeV})^2 [(1+z)/21] \text{eV}$, where $0 < \gamma < 360$ is the Lorentz factor for the electron, and $E_{\gamma,0} = 5 \times 10^{-3} [(1+z)/21] \text{eV}$ is the mean (undisturbed) CMB photon energy. The up-scattering of the CMB photons is the *first step* (of 3 steps) towards reionization. The electron will loose the same amount of energy E_γ , and will cool after $N \sim E_e/E_\gamma = 3 \times 10^5 (E_e/100 \text{MeV})^{-1} [(1+z)/21]^{-1}$ scatterings, corresponding to the cooling time $\tau_C \sim N \lambda_C / c \sim 6 \times 10^4 (E_e/100 \text{MeV})^{-1} [(1+z)/21]^{-4} \text{yr}$. The cooling time for the electron due to collisionally ionizing hydrogen, on the other hand, is $\tau_H \sim 2.9 \times 10^9 (E_e/100 \text{MeV})^{-1} [(1+z)/21]^{-3} \text{yr}$.

By equating $\tau_C = \tau_H$ we infer that decay electrons whose energies are above $E_e > 1[(1+z)/21]^{-1/2} \text{MeV}$ will loose most of their energy to up-scattering the CMB photons. We conclude that only electrons that are produced by sterile neutrinos very near (within ~ 2 MeV) the pion mass could spend a significant fraction of their initial energy on direct collisional H-ionizations. However, CMB photons that are up-scattered by electrons with energies $20[(1+z)/21]^{-1/2} \text{MeV} < E_e < 180 \text{MeV}$ will have final energies

$$13.6 \text{eV} < E_\gamma < 900 [(1+z)/21] \text{eV}. \quad (9)$$

These photons then spend a significant fraction of their energy on reionizing hydrogen. At the low (UV) end of this energy range, the Comptonized photons directly photoionize the neutral hydrogen atoms. Despite the steep decrease of the photo-ionization cross-section ($\sigma_\nu \propto \nu^{-3}$), even at the high (soft X-ray) end of the range, the mean free path of the photons to photo-ionization is a small fraction $(c\sigma_\nu n_H t_{\text{Hubble}})^{-1} \sim$

$0.2(E_e/180 \text{MeV})^3 [(1+z)/21]^{3/2}$ of the Hubble distance. As a result, each photon ionizes a hydrogen atom, and creates a fast secondary photoelectron. The photo-ionization and production of the energetic photoelectron is the *second step* towards reionization. At these low (non-relativistic) electron energies, inverse Compton scattering is negligible compared to collisional ionization, and a fraction $\sim 1/3$ of the initial energy of the photoelectron is subsequently spent on ionizing hydrogen (Shull & van Steenberg 1985; Oh 2001; Venkatesan et al. 2001). This collisional ionization is the *third step* towards reionization.

We conclude that a significant fraction ($\gtrsim 1/3$) of the decay electrons can produce hydrogen ionizations. The maximal number of hydrogen atoms that could be ionized by a single electron, on energetic grounds alone, would be $\chi = E_e/13.6 \text{eV}$. This can be written as $\chi = 5.1 \times 10^6 (M-1)$, where M is again in units of the pion mass. Thus the number of reionized hydrogen atoms is given by

$$n_b = \epsilon \chi n_e^{\text{prod}}, \quad (10)$$

where we have introduced an efficiency factor, $\epsilon \leq 1$, and n_e^{prod} is the number density of electrons (plus positrons) from reaction (3). Using $n_b/n_\gamma = 6 \times 10^{-10}$ and $n_\alpha = 3/11 n_\gamma$, we find that the required efficiency is

$$\epsilon = 0.10 \tau_{15} (M+1). \quad (11)$$

For mixing with muon (or tau) neutrinos the factor in front is 0.071. Note that this efficiency is quite reasonable: using $\epsilon = 1/3$ (see above discussion) and assuming mixing with an electronic neutrino, one can reionize half of the baryons with $\tau_{15}(M+1) = 6.7$ (see Fig. 1).

FIG. 1.— Parameter space (decay time vs. mass) for a decaying sterile neutrino mixed with an electron neutrino, using a reionization efficiency $\epsilon = 1/3$. The right axis shows the redshift corresponding to the given decay time. The solid curve corresponds to ionizing half of the baryons, while the dashed and dotted curves correspond to ionizing a smaller fraction of 1/3 and 1/5, respectively. The star indicates the life-time corresponding to the redshift where the universe should be reionized to the fraction 33% in order to give an optical depth of 0.16.

2.3. Astrophysical Constraints

Let us next turn toward the observational consequences of the decaying sterile neutrinos. First, we can consider how many sterile neutrinos were produced, and whether they will affect the production of light elements (BBN), photon decoupling, or supernova cooling. Using equations (5) and (6), we find

$$\frac{n_s}{n_\alpha} \approx 5 \times 10^{-15} \frac{1}{\tau_{15} (M^2 - 1)}. \quad (12)$$

For masses in the range considered ($140 \text{ MeV} < m < 500 \text{ MeV}$) and for a lifetime several orders around $\tau = 10^{15}$ sec, this is such a small number that none of the three processes above will be affected in any way (Kainulainen et al. 1991; Sarkar 1996; Dolgov et al. 2000; Dolgov 2003). The neutral pions decay immediately into two energetic photons; however, the observed diffuse gamma ray background is several orders of magnitude higher than the signal from the decay products (Kolb and Turner 1990). Furthermore, the mixing angle is so small (see eq. 5), that no terrestrial experiment can detect the oscillations.

A potential observable from reionization at high redshift is the *spectral* distortion of the CMB. The CMB photons have been observed by the *COBE* satellite to obey a nearly perfect Planck distribution. The *COBE* results translate into an upper bound on the energy deposited by the electrons, usually expressed in terms of the limits $|y| < 1.5 \times 10^{-5}$ and $|\mu| < 9 \times 10^{-5}$ on the Compton y parameter and the dimensionless chemical potential, respectively (Fixsen & Mather 2002; Fixsen et al. 1996). As we showed above, in our scenario, a significant fraction of the total energy of the decay electrons is transferred to the CMB. For a sterile neutrino near the pion mass threshold ($1 < M < 1.02$), for which the decay electrons collisionally ionize (and heat) the IGM directly, this transfer occurs by the non-relativistic Compton coupling between the reionized IGM and the CMB. For high energy decay electrons, the transfer occurs in two steps. CMB photons are first up-scattered to UV or soft X-ray energies, effectively removing a small fraction of the photons from the *COBE* range, corresponding to a μ -distortion. Second, this energy is transferred back to the *COBE* range by non-relativistic coupling between the reheated IGM and the CMB (corresponding to a y -distortion).

We therefore compute the total energy in the primary decay electrons (plus positrons), ρ_e , and compare this to the total energy of the CMB, ρ_γ . Using the CMB temperature $T \approx 5 \times 10^{-3} \text{ eV}$ (at redshift $z=20$) we find $\rho_e/\rho_\gamma \approx 7 \times 10^{-6}/(\tau_{15}(M+1))$. Depending on the actual fraction (0.1-0.9) of the mean electron energy that goes into heating the IGM (rather than going into the ionizations and excitations), the number can be even smaller. We conclude that both the μ - and y -distortions are sufficiently small (both $< \rho_e/\rho_\gamma$) that there is no disagreement with the current upper limit from *COBE*. However, the decaying neutrino model presented here should predict a characteristic shape for the distorted CMB spectrum that could be detected in future measurements improving the sensitivity by nearly two orders of magnitude (Fixsen & Mather 2002). Finally, we note that in the stellar reionization case, where the ionizing sources are strongly clustered, the angular *fluctuations* of the spectral distortion can place interesting limits on models (Oh et al. 2003). Since the electrons from the decaying neutrinos are smoothly distributed in space, our scenario avoids this constraint by construction.

3. DISCUSSION

Let us briefly summarize the scenario envisioned in this paper. Sterile neutrinos with masses of about a few hundred MeV were created in the early Universe with an abundance about five orders of magnitude below the number density of baryons. A large fraction, 20–30% of the neutrino’s mass results in decay-produced energetic electrons and positrons. Depending on their energies, these electrons then produce a UV/soft X-ray background by inverse Compton scattering CMB photons. The newly created energetic photons then ionize the IGM either by

direct photo-ionization, or by the collisions between the fast secondary photoelectrons and the neutral hydrogen atoms. For a sterile neutrino mass near (within $\sim 2 \text{ MeV}$) the pion mass threshold, the ionization is by direct electron–hydrogen collisions. As a result, any sterile neutrino with a mass between $140 < M < 500 \text{ MeV}$ would produce relativistic electrons that spend $\gtrsim 1/3$ of their energy on partially reionizing the universe.

In this scenario, the sterile neutrinos produce electrons at a rate $\propto \exp(-t/\tau)$. For sterile neutrino masses near the lower mass ranges considered here, which result in electrons with $E \lesssim 100 \text{ MeV}$ and ultimately produce UV photons, the ionization time is always shorter than the Hubble time, including at redshift $z \sim 1000$. As a result, reionization would track the neutrino decay rate, and neutrinos with these masses would likely lead to a “tail” of the recombination epoch, rather than an episode of 2nd reionization at lower redshift $z \sim 30$ (as in Adams et al. 1998). Such a scenario may be in conflict with existing weak constraints from CMB polarization anisotropies (Kogut et al. 2003; Bean et al. 2003). In comparison, for more massive neutrinos, reionization would be a three-step process, as explained above: (1) the relativistic electrons produce X-ray photons from CMB; (2) the X-ray photons photo-ionize hydrogen atoms, and (3) the fast $\sim \text{keV}$ photoelectron collisionally ionizes many more hydrogen atoms. Of these, (1) and (3) last only a small fraction of the Hubble time for any choice of our model parameters. However, for the upper energy range we considered for the initial relativistic electron, at redshift $z \sim 1000$, (2) will last for $\sim 10^8 \text{ yr}$, a time comparable to the age of the universe at $z \sim 30$. As a result, for these energetic electrons, reionization will occur near $z \sim 30$, producing a 2nd reionization at these lower redshifts.

We note further that the universe cannot be fully reionized at high redshift in this way (Oh 2001; Venkatesan et al. 2001). While the IGM is nearly neutral, the high energy electrons will spend about 1/3 of their initial energy on hydrogen ionizations, and very little energy will be deposited into heating the thermal electrons (Shull & van Steenberg 1985). Once the ionization fraction rises to 50%, the fraction of the electron energy spent on ionizations drops to only few percent, and the fraction spent on heating of the thermal electrons rises to 90% (Shull & van Steenberg 1985). It is therefore a reasonable guess that the electrons will drive the ionization fraction up to $x_e \sim 0.5$. Note that at redshifts of 15–20, the recombination time is a fraction 0.5–0.3 of the Hubble time; we therefore expect recombinations to allow this level of partial ionization to remain. A universe reionized to 30(50)% at redshifts of $7 < z < 31(25)$, but fully reionized at $0 < z < 7$, has an optical depth of $\tau_e = 0.16$ (in our adopted ΛCDM cosmology, conservatively ignoring any contribution to the opacity from He^+ or He^{++} which recombine more rapidly than hydrogen). We conclude that a scenario in which a decaying particle produces an early boost of reionization, followed by full reionization by stars, is therefore plausible, and can account for the *WMAP* optical depth.

Our scenario implies that warm dark matter (WDM) models are not ruled out. This is not in contradiction with the results of Barkana et al. (2001), Spergel et al. (2003) and Yoshida et al. (2003), since all of these studies assumed that reionization was done by stars alone. The possibility of a sterile neutrino saving the option of WDM is rather peculiar, because the only (to our knowledge) natural WDM candidate is, in fact, another sterile neutrino (Dodelson & Widrow 1994; Dolgov & Hansen 2001; Abazajian et al. 2001), which is constrained to have a mass of

a few keV (Abazajian et al. 2001; Hansen et al. 2002). One should mention that more inventive WDM candidates certainly exist (see e.g. Baltz & Murayama 2001; Boehm et al. 2002).

Thus, with a minimal extension of the standard model with two sterile neutrinos (one with a mass of about a keV, and another with a mass of a few hundred MeV), one obtains the right abundance of dark matter, and achieves an early boost of reionization. WDM models may be attractive in helping to solve some possible problems of CDM on small-scales, although many issues remain to be clarified (see summary in, e.g., Haiman et al. 2001).

A very important question is whether we will be able to distinguish between early stellar reionization models, and the scenario described above. It was shown by Kaplinghat et al. (2003) that two years of polarization data from *WMAP* can distinguish between a scenario with full reionization up to $z = 6.3$, and a model with an additional 50% reionization between $z = 20$ and 6.3 . *Planck* will do even better in just one year, namely distinguishing between 0% or 6% reionization between $z = 20$ and 6.3 . For related studies, see e.g. (Doroshkevich et al. 2003; Naselsky & Chiang 2003). Specifically, Haiman & Holder (2003) and Holder et al. (2003) showed explicit examples of different reionization histories which produce the same optical depth $\tau = 0.16$, but can be distinguished from each other by *Planck* polarization measurements at $> 3\sigma$ significance. Based on these studies, we are confident that the model discussed above can be constrained or confirmed within a few years. The reionization history in the decaying neutrino model could possibly be mimicked by ionization caused by an early generation of stars that produces X-rays and therefore fast photoelectrons (Oh 2001; Venkatesan et al. 2001). However, this “degeneracy” can be broken by examining small angular scale Sunyaev-Zeldovich fluctuations, which should be strong in the stellar case (Oh et al. 2003), but nonexistent in our scenario.

There are many issues we have not touched upon in this simplified treatment. For example, hydrogen recombinations are significant at high redshifts, and one would have to convolve the recombination rate in the IGM with the neutrino decay rate, in order to compute the actual ionization fraction as a function of redshift. While we do not expect such a computation to change our main conclusions, it will allow predictions to be made about the precise evolution of the ionization and thermal history of the IGM, as well as the resulting spectral signatures on the CMB.

4. CONCLUSIONS

In this paper, we studied the possibility of a reionization history that consists of two completely independent steps. The first step is provided by fast electrons from a decaying sterile neutrino. The abundance and mass of this sterile neutrino is such that up to 50% of the universe can be reionized around a redshift of $z = 25$. Subsequently, standard (population II) star formation can complete reionization at $z \sim 6-7$. This scenario can give an electron scattering optical depth of $\tau = 0.16$, in agreement with *WMAP* observations. In such a scenario, the possibility of warm dark matter still exists, since stars only need to complete the reionization around redshift of $z = 7$ to comply with the observed Gunn-Peterson opacities of high redshift ($z \sim 6$) quasars. The model proposed here can be tested in future studies of the CMB, both by inferring the reionization history (evolution of the ionized fraction) from post-*WMAP* polarization data, and by studying the deviation of the CMB spectrum from a pure black body shape.

We thank Ted Baltz, Zurab Berezhiani, Asantha Cooray, Martin Haehnelt, Peng Oh, Subir Sarkar, and an anonymous referee for useful comments that improved this paper. SHH thanks the Tomalla foundation for support
